The bats recorded from Iceland, the Faroe Islands, the Shetland Islands, the Orkney Islands, and North Sea installations are reviewed to the end of 2012. In total 12 species have been positively identified, while a considerable proportion of all records are sightings of unidentified bats. Eight of the species are European in origin and four originate from the New World. The largest number of species (8) has been recorded in Iceland, but the greatest number of individuals (180) has been found in Orkney. The bat invasion on the Faroe Islands in 2010 is without precedence, when 70 observations of a minimum of 45 individuals were noted. Most bat observations in the study area occurred in the autumn, with fewer in the spring. Most observations were of single animals, but there were also sightings of up to 12 individuals. There has been a marked increase in bat records in the past three decades. We discuss whether this is a real increase, or due to improved communications, increased public awareness, increased shipping, changes in weather patterns and/or the effects of climate change. All factors appear to be involved.

Key words: Iceland, Faroes, Shetlands, Orkneys, North Sea, vagrancy, ship-assistance, climate change, invasion, identification problems

INTRODUCTION

The order Chiroptera is widespread through most parts of the World. The greatest proportion of families, genera and species are found in the tropics and sub-tropics, with a lower proportion in temperate zones. Within temperate zones, the number of species decreases with increasing latitude. In temperate zones, insectivorous bats are restricted to those areas with good supplies of food to sustain them through the spring and summer breeding periods and enable them to build up adequate fat reserves in the late summer and autumn ready for hibernation through the winter (Yalden and Morris, 1975; Hill and Smith, 1984; Rolland *et al.*, 2014).

Migratory behaviour and vagrancy are particularly well-known in birds and bats (Ahlén, 1997; Hutterer *et al.*, 2005; Ahlén *et al.*, 2009), in which the ability to fly makes it easier to disperse outside their normal range. Bats employ a variety of strategies to make best use of the available habitats. Some species occupy relatively small territories, travelling

only short distances in search of food and between breeding roosts and winter hibernacula, while other species migrate for medium to long distances, in order to exploit resource-rich areas.

The North East Atlantic islands, comprising Iceland with its fluctuation between subarctic winters and temperate summers and the Faroe, Shetland and Orkney islands with temperate but cool winters and summers, with one exception do not have resident populations of bats. Nor are the islands considered to be on normal migration routes, although stragglers do reach them on occasion. The species involved and the frequency of these occurrences undoubtedly depends on the distance from their normal range, but a number of other factors, such as population numbers, vagrancy, and unintentional transport by humans, are also important. In the long run, global environmental changes such as climate change may also modify traditional distribution patterns.

The present study examines records of bats from the North East Atlantic islands of Iceland and the

Faroe Islands to the end of December 2012, including those reported in previous publications (Koopman and Gudmundsson, 1966; Petersen, 1993, 1994; Baagøe and Bloch, 1994). Comparisons are made with published data on bats recorded from the Shetland Islands and the Orkney Islands, off the north coast of Scotland, as well as oil and gas installations in the North Sea.

Information is provided on all species recorded; the locations of the records are mapped and the species composition, distribution and seasonal occurrence analysed. The possible reasons for the marked increase in occurrence of bats, including the unusual invasion of the Faroe Islands in 2010, are discussed.

MATERIALS AND METHODS

This study summarizes all available information to the end of 2012, based on specimens of bats preserved mainly in the collections of the Náttúrufræðistofnun Íslands (Icelandic Institute of Natural History [NÍ]), with single specimens respectively at the Natural History Museum of Kópavogur and at Vestmannaeyjar Primary School (Appendix I). Available Faroese specimens are preserved in the scientific collection of the Føroya Náttúrugripasavn (Faroese Museum of Natural History [FN]) (Appendix II). It also includes published records of bats from the Orkney Islands, Shetland Islands, and from oil and gas installations in the North Sea (Appendices III–V). The map (Fig. 1) shows the overall area covered by this study.

The specimens preserved in the collections of NÍ and FN have been acquired opportunistically over many years by interested members of the public. Specimens were identified by the use of literature available at the time of acquisition and by consultation with staff in other European museums containing

international collections of bats. Photographs are available as proof for some bat sightings, although the species could not be established in most cases. Sound recordings using a Pettersson Ultrasound detector D100 have also been used in the Faroe Islands. This detector type may only be used to locate flying bats but not for species identification. In Iceland and the Faroe Islands, sightings were assessed by interviews and requests for photographs because of the problems that exist due to the general public confusing bats with insects and birds. Insects which are especially likely to cause confusion are the larger moths (Jensen and Sivertsen, 2010), while small petrels (seabirds) have an erratic flight similar to that of bats and may be easily misidentified at a distance.

Records of bats from the Orkney and Shetland Islands, and from North Sea installations were obtained by literature searches. Records of bats from the Orkney Islands have been particularly well documented over the last two decades, as a result of observations by members of the very active Orkney Field Club (Booth, 1992–Booth, 2012). Information for the Shetland Islands was initially derived from the website of the Shetland Biological Records Centre [SBRC] (<http://www.nature-shetland.co.uk/brc/bats.htm>) and (<http://www.nature-shetland.co.uk/naturelatest/archives/>), and for North Sea installations from Swift (2004); where possible these records have been traced back to the original references (Appendices III–V).

Coordinates for localities on Iceland were determined using Google Earth (<http://earth.google.com>), while the website <http://www.findlatitudeandlongitude.com> was used for localities on the Faroe Islands. Coordinates for localities on the Shetland and Orkney Islands were principally located by reference to the gazetteer (Ordnance Survey, 1999) supplemented by Google Earth. Coordinates for North Sea installations not included in original references were determined using maps of North Sea oil and gas fields (<http://www.acorn-ps.com/web/page/oilgas/nsfields/snsmap.htm> and http://tools.decc.gov.uk/en/content/cms/tools/quad_maps/quad_maps.aspx). Distribution maps were prepared using DMAP (<http://www.dmap.co.uk>).

RESULTS

To the end of December 2012, 12 species of bats all belonging to the family Vespertilionidae have been recorded from the area of study. Four originate from the New World: *Eptesicus fuscus* (Palisot de Beauvois, 1796), *Lasiurus cinereus* (Palisot de Beauvois, 1796), *Myotis lucifugus* (LeConte, 1831), *M. septentrionalis* (Trouessart, 1897); eight are European: *E. nilssonii* (Keyserling and Blasius, 1839), *E. serotinus* (Schreber, 1774), *Nyctalus leisleri* (Kuhl, 1817), *N. noctula* (Schreber, 1774), *Pipistrellus nathusii* (Keyserling and Blasius, 1839), *P. pipistrellus* (Schreber, 1774), *Plecotus auritus* (Linnaeus, 1758) and *Vespertilio murinus* Linnaeus, 1758 (see Appendices I–V and Table 1). A considerable proportion of the individuals are unidentified. This is explained by the variable nature of the records, for while only a third of the bat records from Iceland were sightings, this accounted for the majority (76%) of those in the Faroe Islands. Just over half of the Icelandic records are of bats which were found alive, while this category was 16% for the Faroe Islands. For the Orkney Islands, although only 8% of the records are of identified individuals, 39% of the records are of sightings identified to species with the use of bat detectors and only 11% are sightings. In contrast all of the published records for North Sea installations are identified to species.

All the records for North Sea installations and the Shetland Islands were of single animals. In Iceland

31 of the records (94%) were of single animals, with one instance of two animals and another of six. This differs from the Faroe Islands, where 74 records (77%) were of single animals, 21 of two (10%), three (5%), or four (6%) animals. In the Orkney Islands four of the species were recorded as single animals, but there were multiple sightings of *P. pipistrellus* ranging from three to 12 animals.

Species Accounts

Information on each species is given below and those found in each study site are mapped in Figs. 2–6.

Eptesicus fuscus

A single individual was found in Iceland in a container of bananas from South America. This species occurs from South Canada to Colombia and North Brazil; Alaska, Greater and Lesser Antilles, Bahamas (Simmons, 2005). There are two records from England of imported specimens (Hutson, 2008a).

Eptesicus nilssonii

Two individuals were recorded from the Faroes and North Sea. It is considered to be the most common and widespread species of bat in Norway and Sweden, where it has been recorded north of the Arctic Circle (Rydell *et al.*, 1994; Syvertsen *et al.*, 1995; Ahlén, 2011; Frafjord, 2013). It occurs above

64°N in northern Finland (Siionen and Wermundsen, 2008). There are very few records in England (Hutson, 2008b).

Eptesicus serotinus

One of the two individuals was found in timber storage in the Faroes. Occurs throughout Europe as far north as 55°N (Dietz *et al.*, 2009) and also in southern Sweden (Ahlén, 2011). In England it is found mainly in the southeast, but also in central and northwest England and Wales (Entwistle *et al.*, 2001; Hutson, 2008b).

Lasiurus cinereus

A single individual was found alive in Orkney (Wolley, 1849, 1850), as were three of the individuals recorded from Iceland. Occurs in Canada, throughout the USA, Mexico, Guatemala, most of

Islands: 1 — Mainland, 2 — Yell, 3 — Unst, 4 — Whalsay, 5 — Fair Isle

South America, Bermuda and the Galapagos Islands (Simmons, 2005). There is an extralimital record on Southampton Island at 64°20'N (Hitchcock, 1943). Cryan (2003) provided information on distribution patterns throughout the year in North America.

Myotis lucifugus

One of the two individuals recorded from Iceland was found on board a ship arriving in Reykjavik harbour from the east coast of the USA. This species

has a broad range to a maximum latitude of 66°34'N in the USA and Canada (Pierson, 1998), occurring from Labrador and Newfoundland in Canada to Alaska, southern California, northern Arizona and northern New Mexico in the USA (Simmons, 2005). There is a single record from England of an imported specimen (Hutson, 2008a).

Myotis septentrionalis

The 1981 specimen was found on board a ship that came from the east coast of the USA, on the same occasion as an individual of *M. lucifugus* and four other bats that were discarded before they could be identified. The other Icelandic individual flew into a house and died, but could have arrived by ship at the nearby Hafnarfjörður harbour. Found in Eastern United States and Canada west to British Columbia, E Montana, E Wyoming and south to Alabama, Georgia and Florida Panhandle (Simmons, 2005), to a maximum latitude of 61°25'N (Pierson, 1998).

Nyctalus leisleri

The individual from Iceland was found in a storage bunker. Occurs throughout western Europe to nearly 57°N, however there are no records from Denmark and Scandinavia, except for southern Sweden (Simmons, 2005; Dietz *et al.*, 2009; Ahlén, 2011). Although rare, this species occurs throughout the British Isles, mainly in central and southern counties of England, also in south western Scotland, a few records from northeast Scotland and it is widespread and common in Ireland (Haddow and Herman, 2000; Entwistle *et al.*, 2001; Sheil *et al.*, 2008).

Nyctalus noctula

The Icelandic record is of an individual captured on board a cargo vessel. The species is widespread in Europe to the Urals and the Caucasus (Dietz *et al.*, 2009). It has been recorded rarely in southern Norway (Syvertsen *et al.*, 1995) and has an uneven distribution in central and southern Sweden (Ahlén, 2011). The species is widespread in England, Wales and southwest Scotland but is absent from Ireland (Haddow and Herman, 2000; Entwistle *et al.*, 2001; Mackie and Racey, 2008).

Pipistrellus nathusii

This is the only species of pipistrelle reliably recorded from North Sea installations, Shetland, Faroes and Iceland, where it is also the most commonly recorded species of bat (Table 1; Figs. 2–3, 5–6). It has also been recorded on the Orkneys (Fig. 4), but here it is less frequently encountered than is

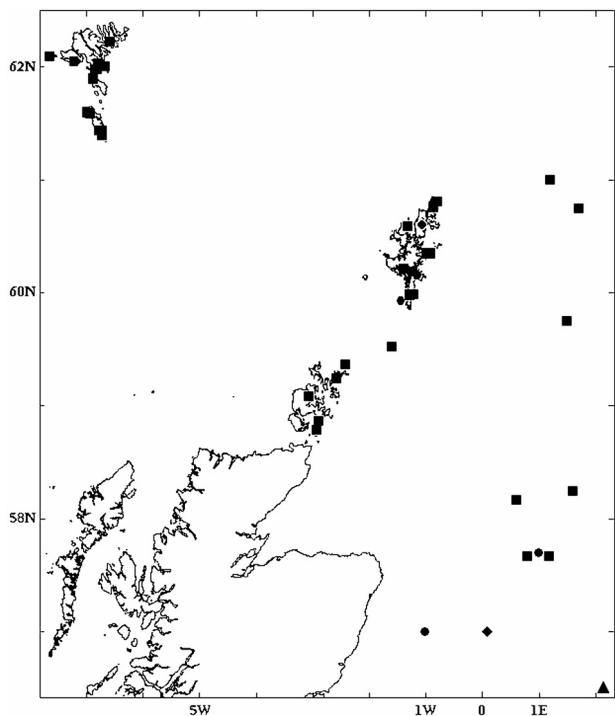

FIG. 6. Map showing distribution of species of bats recorded from North Sea installations. ■ — *P. nathusii*, ● — *V. murinus*, ▲ — *N. noctula*. Location in the North Sea where both *P. nathusii* and *V. murinus* have been recorded is indicated by ♦. Details of the records of species on the Faroes, Shetland and Orkney Islands are shown in Figs. 2–4

P. pipistrellus (7% of the total *P. pipistrellus* and *P. nathusii* records). It is possible that some of the earlier unidentified *Pipistrellus* records in all study areas are representatives of this species.

Occurs in western Europe, from southern Scandinavia southwards to France and northern Spain and eastwards to the Urals and Caucasus (Dietz *et al.*, 2009). It has been recorded in Norway (Syvertsen *et al.*, 1995; Swenson *et al.*, 2010) and is found in central and southern Sweden as far north as 61°21'N (Ahlén, 2011). Occurs in southern and eastern Scotland, most of England and Wales, and eastern and central Ireland (Russ *et al.*, 2001; Russ, 2008).

Pipistrellus pipistrellus

Reliable records of *P. pipistrellus*, based on professionally identified specimens and sound recordings of bats with echolocation calls at 45 kHz, have only been obtained from the Orkney Islands (Table 1 and Fig. 4), where it is by far the most commonly recorded species (75% of the total records of *Pipistrellus*). Although the Orkney Islands may be considered marginal for the existence of resident

bats, there is evidence of summer roosts of *P. pipistrellus* from various locations from 1994 onwards (Holmes, 1994; Holmes *et al.*, 1995; Booth, 1995–2011; see Fig. 7).

Widespread in Europe, more common than *Pipistrellus pygmaeus* (Leach, 1825) in central Europe, but rare or absent in the Netherlands and Scandinavia (Jones and Racey, 2008; Ahlén, 2011). Details of distribution remain uncertain on mainland Europe. Occurs throughout the British Isles (Barlow and Jones, 1999; Jones and Racey, 2008).

Plecotus auritus

Records from Shetland and Orkney, including one individual observed over a period of eight days (Booth, 1989). Occurs throughout Europe (Dietz *et al.*, 2009). In Scandinavia it is found throughout the lowlands of southern Norway as far north as 63°25'N (Syvertsen *et al.*, 1995), is common in southern and central Sweden (Ahlén, 2011) and occurs above 64°N in northern Finland (Siivonen and Wermundsen, 2008). Widespread in the British Isles, except for the far north of Scotland (Haddow and Herman, 2000; Entwhistle *et al.*, 2001; Entwhistle and Swift, 2008).

Vespertilio murinus

There are more records of this species than of other European bats, apart from *Pipistrellus*. Both of the Icelandic records were of live animals, one of which flew into the bridge of a cargo vessel. Occurs in Europe eastwards and northwards from eastern France (Dietz *et al.*, 2009). It occurs in scattered coastal localities in southern Norway as far north as c. 61°56'N (Syvertsen *et al.*, 1995) and also has an uneven distribution in southern Sweden (Ahlén, 2011). Occasional records from the British Isles are considered to be of vagrants and migrants (Racey *et al.*, 2008).

The Invasion in 2010

The unprecedented bat invasion in the Faroe Islands occurred from September to the beginning of November 2010 (Fig. 8). Over a period of seven weeks, 70 observations were recorded and, although some of these observations were possibly of the same individuals, a minimum of 45 individual animals were involved. Two bats were identified respectively as *V. murinus* and *Pipistrellus nathusii*, but no further bats were identified to species.

During the invasion period, two unidentified bats were recorded in Iceland and three in Shetland,

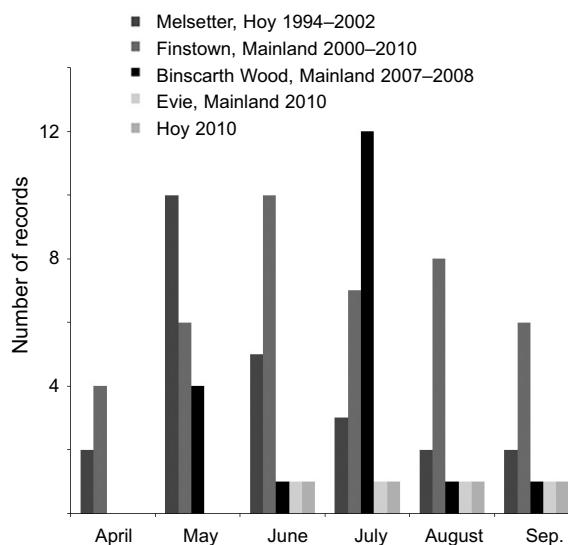

FIG. 7. Seasonal occurrence of records of *P. pipistrellus* from selected localities in Orkney, showing changes in location over the years from 1994 to 2010. The vertical axis represents the number of records for each month from April to September

which may signify a connection with the phenomenon in the Faroes. None were recorded on North Sea installations at this time.

Seasonal and Frequency Data

The majority of *P. nathusii* records occur in the autumn and winter in marked contrast to the occurrence of *P. pipistrellus* mainly in late spring to early autumn (Fig. 9). For all other species of bats (Fig. 10), a similar pattern may be seen to that of *P. nathusii*, with the majority of records occurring in the autumn. The frequency of occurrence of bats in all study areas is given in Table 2, which shows a marked contrast between the low number of records in the first two decades and those in the three succeeding decades.

DISCUSSION

Monitoring of all wildlife may be considered the duty of any independent nation and the incursion of any non-native species is a matter of interest for a variety of reasons. Bats are very rare vagrants on the north east Atlantic islands and North Sea installations. Further north and west, bats have also occasionally been observed on Greenland, and are understood to have been blown over from North America according to Møbjerg and Rosing (2001). These authors state that the bats have both an East Greenlandic name "Avangiarlik" (the one which

resembles a lemming) and in West Greenland, "Imangertaq" (the one which has been silenced). This indicates that bats have been recorded on both sides of the huge Greenland ice-shield, although individual records with locality and date do not seem to be available.

Most of the bats found in Iceland were recorded in the south and southwest. The largest number has been found in the capital city of Reykjavik, where most of the population lives and where most of the international shipping and air traffic is received. Many of the bats were recorded under such situations that point to assisted passage, either with imported goods, on board ship or in storage containers. Others found inside houses, or alive outside may also have been assisted rather than arriving independently.

As far as the other island groups are concerned, the inadvertent transport of bats by humans is apparently of less importance. In the Faroe Islands most bats have been observed when catching insects attracted to the street lights in the small settlements around the entire Faroe Islands. While there are four records of bats on Mainland, Shetland from the port

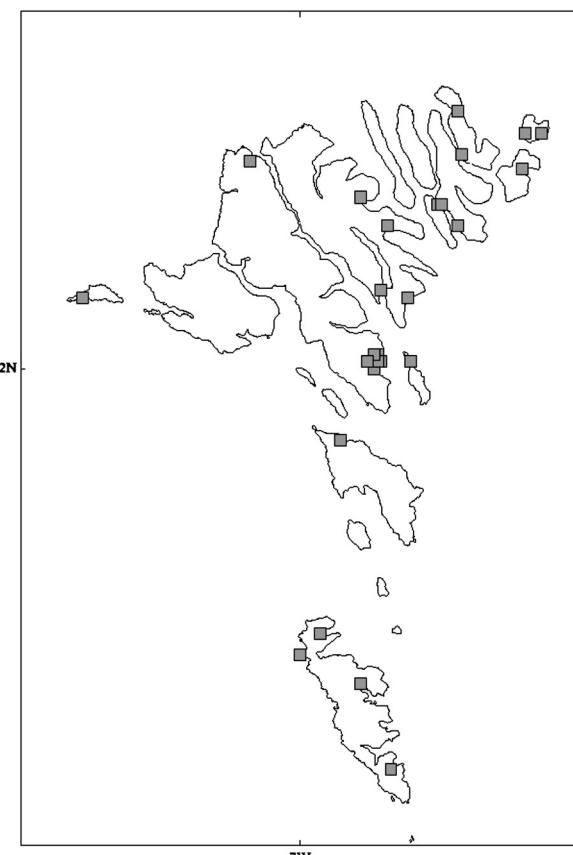

FIG. 8. Map showing the inundation of bats on the Faroes during September to November 2010

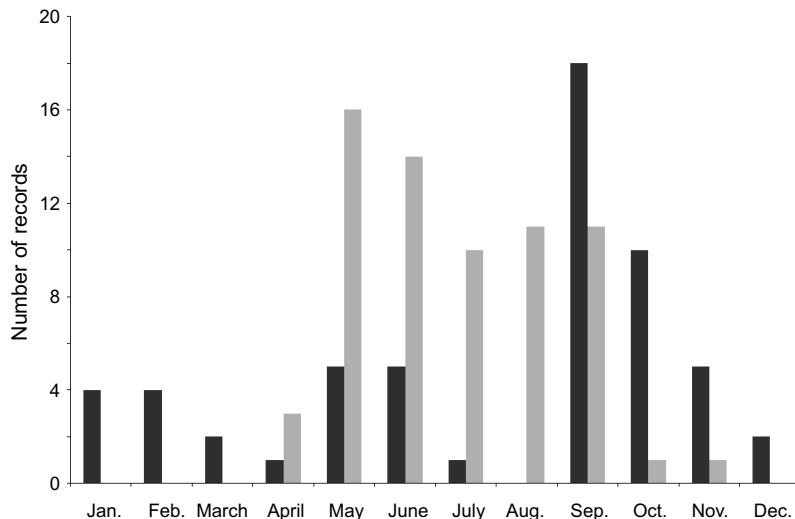

FIG. 9. Comparison of the seasonal occurrence of records of *P. nathusii* (■) from the combined study areas, with those of *P. pipistrellus* (▨) from Orkney. The vertical axis represents the number of records each month

and capital and two from the main airfield, other records are more or less randomly distributed in the islands. Similarly while there are records of three species on South Ronaldsay, the closest island to the Scottish mainland, there are no obvious connections in Orkney to the inadvertent transport of bats by humans.

Movements

The bats recorded from the study areas may be broadly divided into sedentary or migratory species. The tendency to vagrancy and migratory behaviour, which greatly varies between bat species, no doubt

has much bearing on whether bats reach the islands without assistance.

Sedentary Bats

All three species of *Eptesicus*, *P. pipistrellus*, *P. auritus* and *M. septentrionalis* are regarded as largely sedentary species of bats. Both *E. nilsonii* and *E. serotinus* have small home ranges, moving only short distances between roosts, but with occasional longer distance dispersal flights in Europe (Hutterer *et al.*, 2005; Hutson, 2008b). *Eptesicus fuscus* is a more or less sedentary species according to Hutson (2008a). *Plecotus auritus* is considered to

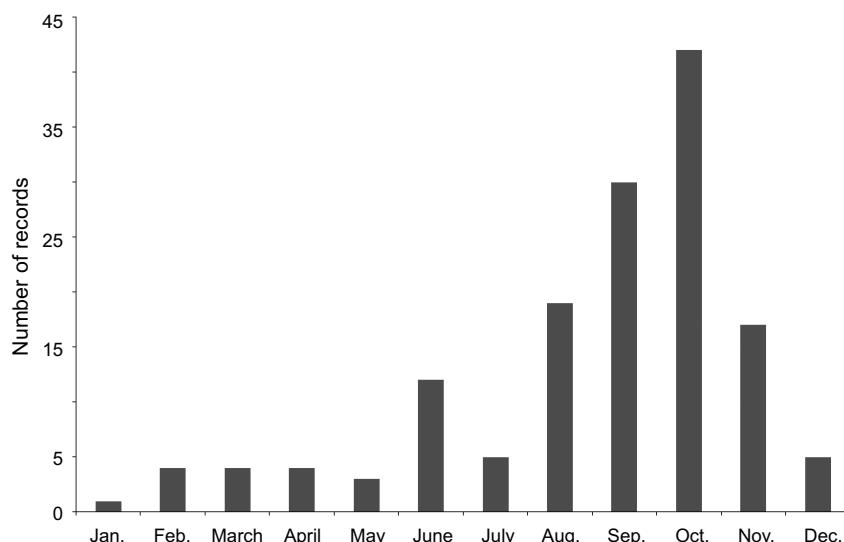

FIG. 10. Comparison of the seasonal occurrence of all records of bats, other than *Pipistrellus*, from the combined study areas. The vertical axis represents the number of records each month

TABLE 2. Frequency of occurrences in all study areas from 1960 to 2009, grouped into ten year periods, and for three years from 2010 to 2012. Figures in bold indicate the peak records for each of the study areas

Area	Records	1960–69	1970–79	1980–89	1990–99	2000–09	2010–12
North Sea	All records	1	0	6	15	6	0
	<i>P. nathusii</i>	0	0	4	14	2	0
Orkney	All records	0	3	2	60	74	37
	<i>P. nathusii</i>	0	0	0	1	2	2
Shetland	<i>P. pipistrellus</i>	0	0	0	15	39	16
	All records	1	2	13	12	11	13
	<i>P. nathusii</i>	0	0	4	7	0	0
Faroes	All records	0	0	2	10	25	79
	<i>P. nathusii</i>	0	0	2	3	7	5
Iceland	All records	2	2	2	2	12	5
	<i>P. nathusii</i>	0	1	1	0	3	1

be a relatively sedentary species (Hutterer *et al.*, 2005; Baagøe, 2007; Entwistle and Swift, 2008). Corbet (1970) commented that a specimen found in the autumn on a lightship about 48 km east of Norfolk, UK may have originated from the continent, as this coincided with a massive fall of birds from Scandinavia. Although recorded rarely in the study areas and then at long intervals, there are more records of this species than of other sedentary species. The New World *M. septentrionalis* is a short-range migrant reported to travel a distance of up to 56 km between the summer habitat and winter hibernacula (Caceres and Barclay, 2000). There are very few records from the study areas of any of these sedentary species and only *E. nilsonii* has been recorded from an oil rig. Most of these are believed to be vagrants, whose presence may be attributed to inadvertent transportation by humans.

Most populations of *P. pipistrellus* in central Europe are sedentary, travelling only short distances between winter and summer roosts, although this species may be more migratory in eastern Europe (Hutterer *et al.*, 2005; Jones and Racey, 2008). This is the only species with apparent breeding roosts so far North in Britain, although it has only been recorded on Mainland and Hoy, the largest of the Orkney Islands. The locations of summer roosts have changed over time, sometimes two roosts co-existing for several years, suggesting that there may be sufficient bats for the formation of splinter groups, which may or may not be sustainable depending on conditions. While the status of this species on the Orkneys may be accepted as that of a resident, populations here may be vulnerable, as they are at the northern boundary of their distributional range in the British Isles.

There is little available information on *P. pygmaeus*, because most predates the taxonomic

separation from *P. pipistrellus*, however Sztencel-Jablonka and Bogdanowicz (2012) observed that *P. pygmaeus* was more migratory than *P. pipistrellus*. Details of the distribution of this species remain uncertain but it is widespread in Europe and southern Scandinavia and, while both species are sympatric over most of their range, *P. pygmaeus* may be the more common of the two on the margins of continental Europe (Racey *et al.*, 2007). It occurs throughout the British Isles but is apparently less common than *P. pipistrellus* in northern mainland Scotland (Barlow and Jones, 1999; Jones and Racey, 2008). To date this species has not been recorded from any of the study areas but could conceivably be included amongst the records of unidentified *Pipistrellus*. There is one equivocal reference to a bat detector recording in Orkney of a pipistrelle calling in the 50–55 kHz range which was attributed to *P. pipistrellus* (Booth, 2010), although calls above 52 kHz are in the range of *P. pygmaeus*. In this study it has been included as an unspecified *Pipistrellus*, while the early record of *P. pipistrellus* (Spence, 1909) could represent either species. The situation becomes even more complicated in light of the recent evidence of hybridisation between the two species in continental Europe (Sztencel-Jablonka and Bogdanowicz, 2012).

Migratory species

Nyctalus leisleri is considered to be a long-distance migrant, showing regular seasonal NE to SW movements between the summer and winter habitats in Europe (Hutterer *et al.*, 2005; Sheil *et al.*, 2008). It seems unlikely that migration was a factor in most of the records in the study areas which are mainly in the summer. However strong winds may have affected dispersal in some instances (Corbet, 1970).

In contrast *N. noctula* is not considered to be such a long range migrant; it is migratory in eastern Europe, but probably less so in western Europe (Strelkov, 1969; Hutterer *et al.*, 2005). Information on migratory activity in Scandinavia has been recorded by Ahlén (1997), Baagøe (2007) and Ahlén *et al.* (2009). Populations are not known to migrate from England in the winter and records from the Orkneys, Shetlands and North Sea installations are regarded as vagrants from Europe (Mackie and Racey, 2008), some perhaps originating from Scandinavia.

Pipistrellus nathusii is known to be a seasonal long-distance migrant in Europe (Strelkov, 1969; Ahlén, 1997, 2011; Pētersons, 2004; Hutterer *et al.*, 2005; Ahlén *et al.*, 2009). Ahlén (1997) reported dispersal and migratory behaviour in this species in late August and early September. Some of these bats were observed to fly out over the open sea in a southern or south-westerly direction and specimens marked in Sweden have been recorded in Germany and Belgium.

Pipistrellus nathusii was first recorded from the British Isles by Stebbings (1970) and for the next two decades it was considered to occur only as an occasional vagrant in Britain. With an increase in the number of records in the late 1980s, it was subsequently considered to be a winter migrant (Speakman *et al.*, 1991; Hutson, 1993). More recently the discovery of three summer maternity colonies in England and Northern Ireland (Hutson, 1997; Russ *et al.*, 1998, 2001) means that this species in Britain and Ireland is now considered to consist of both a resident breeding population present throughout the year, and a migratory population present during autumn, winter and spring (Russ, 2008). The increasing number of records in the study areas over the same period mirrors the situation in mainland Britain, with similar seasonal peaks for sightings and records in September and October, coinciding with autumn migratory behaviour. Therefore, although in these areas the records are more likely to be of vagrants, it is conceivable that some could be migrants. Most of the specimens recorded from Iceland were probably ship-assisted, although the specimen from the island of Heimaey could have been a storm-borne migrant.

Vespertilio murinus is a long-distance migrant normally spending the summer in northern, central and eastern Europe and flying generally in a south-westerly direction to southern Europe to hibernate (Hutterer *et al.*, 2005; Stebbings *et al.*, 2007). In southern Sweden a few individuals were recorded in

the autumn leaving land and flying out over the sea (Ahlén, 1997). There has been an increase in records in the British Isles since 1980, predominantly in the autumn and spring suggesting that migrants are sometimes deflected from continental Europe (Racey *et al.*, 2008). This is also possible for records from Shetland and North Sea installations, even for records from the Faroes. The specimen recorded from NE Iceland could possibly be a storm-assisted migrant.

Lasius cinereus is a fast flying, highly migratory species that has been recorded in Orkney and Iceland in autumn and winter (Stebbins, 1986; Stebbings *et al.*, 2007). Three of the specimen records from Iceland were from small, remote locations on the southern coast of Iceland, so ship-assisted passage was considered unlikely (Koopman and Gudmundsson, 1966). These authors also mentioned that meteorological records of storm tracks just prior to the October records of 1957 and 1964 indicated winds suitable to carry bats from eastern Canada to south western Iceland, which was further substantiated by a meteorologist (Jakobsson, 1967).

Although Wolley (1849, 1850) was of the opinion that the Orkney record was of a ship-assisted individual, Hill and Yalden (1990) and Yalden (2008) pointed out that at least two American land-birds were also recorded in western Europe in the autumn of 1847. It seems highly likely therefore that the Orkney and Iceland records are of bats storm-carried whilst migrating, although, in the case of the Orkney record, at least partial ship-assisted passage may not be excluded.

Myotis lucifugus is a medium-range migrant with movements of more than 300 km to hibernation sites (Hutson, 2008a). The record in August could be of a stray migrant, although Koopman and Gudmundsson (1966) concluded that it was more probable that this immature bat was ship-assisted to Reykjavík harbour.

Frequency of Occurrence

The apparent increase in the occurrence of bats, raises the following questions that need to be addressed.

(a) Is there a real increase in records? The results show (Table 2) that there has been a measurable increase in records for four of the five study areas (Iceland, Faroes, Shetland and Orkney).

(b) Is the increase due to improved communication? In such isolated regions as most of the study areas, until relatively recently internal communication was limited and communication with the

external world restricted, which may have hampered the notification of rare animals like bats to the scientific world. This does not apply to the situation in Iceland however, which has had good internal communication for considerably longer and regular external communication for up to a century.

(c) Is there an increased awareness? There has always been an interest in the news of unusual sightings of animals, witness the early records of bats in Shetland in 1774 (Low, 1879), 1815 (Laing, 1815), and 1904 (Tulloch, 1904); in Orkney in 1847 (Wolley, 1849) and 1908 (Spence, 1909); and in Iceland in the 18th century (Pennant, 1784), circa 1817 (F. Faber, unpublished diary held in the Archives of the Kongelig Bibliotek, Copenhagen) and 1936 (Petersen, 1994). There are no similar early records in the Faroese literature and indeed Degerbøl (1940) makes no mention of them.

It appears that bats have become more common over the last decades. For example amateur naturalists have lived on Nólsoy in the Faroe Islands for the last 150 years, yet the first bats were not observed there until 1987, increasing to 25 records in the period from 2000 to 2009. The dramatic increase in records for Orkney from the few in the 1970s and 1980s to much greater numbers in the 1990s and 2000s, may be due in part to greater awareness and involvement of local naturalists and others inspired by a very keen recorder (Booth, 1979, 1980, 1989, 1992–2012), but is also likely to be a true reflection of the increase since Orkney Field Club publications date from 1968. Similarly researchers at NÍ have taken an interest in recording bats in Iceland, probably from as early as 1889 when the Icelandic Natural History Society with its natural history museum was established. However the records remained steadily at two per decade from the 1960s to the 1990s, with a marked increase from 2000 to 2012.

(d) Is there an increase in shipping traffic? Shipping traffic into Iceland, and more recently the use of containers to transport all manner of goods has increased considerably over the last few decades. Air traffic has also increased and is an important source of goods transport for all study areas. At least ten of the records from Iceland are believed to have been associated with shipping, and one possibly with air transport. In the Faroe Islands only one bat is presumed to have been imported with timber and there are no other Faroese observations to suggest that bats have arrived with either aircraft or ship.

(e) Is the apparent increase due to changes in weather patterns and the effects of climate change? Unusual weather patterns have been invoked in the

past to account for the occurrence of vagrants, such as that of the specimen of *L. cinereus* in Orkney, which coincided with that of North American land birds in western Europe. The relationship between bat occurrences and weather patterns was identified in Iceland in the 1960s (Koopman and Gudmundsson, 1966; Jakobsson, 1967). The 2010 invasion of the Faroes also included birds from the USA, Europe and the Far East, and European Lepidoptera. During the same period, a number of European Lepidoptera reached south east Iceland, borne there on a warm south-easterly wind (Erling Ólafsson, personal communication). It is difficult to reach any conclusions concerning the possibility of changes in environmental factors affecting the situation in the Faroes at this time, for although September and October were amongst the seven months that were warmer than normal that year (Cappelen, 2011) weather maps for the Faroes showed no unusual wind conditions at that time (<http://www.dmi.dk/faeroerne/arkiver/vejrarkiv/>). An analysis of the occurrence of bats, insects and vagrant birds and weather patterns is much needed.

It is important to distinguish the influence of occasional unusual weather patterns from overall trends in climate. The evidence about long term changes in weather patterns linked to global environmental change is still fragmentary but nevertheless strongly indicated, and evidence to demonstrate the ecological response of species to climate change is accruing in many taxa (Thomas and Lennon, 1999; Parmesan *et al.*, 1999; Visser and Holleman, 2001; Walther *et al.*, 2002; Parmesan and Yohe, 2003; Sherwin *et al.*, 2013). As far as the study areas are concerned, Cappelen (2011) reported that the decade from 2001–2010 was the warmest in the Faroes since measurements began in 1890.

The status of *P. nathusii* in the British Isles has changed over more than four decades from vagrant to that of a resident and winter migrant. This may represent a range extension which could conceivably be linked to climate change, but may just be a question of mistaken identity in the past and an increase in skilled recorders since the mid-1980s (Russ *et al.*, 2001). The increase in records of *P. nathusii* in the study areas however, suggests that migrating bats are more often in areas where they are more prone to being swept off-course. In a recent study, this species has been used to demonstrate range expansion linked to climate change in the UK (Lundy *et al.*, 2010). These authors mapped the change in habitat suitability for this species from 1980 to 2000 based on UK Meteorological Office

data and modelled the projected change in habitat suitability from 2020 to 2080. The presence of resident *P. pipistrellus* on Orkney may also be regarded as a range extension, implying that overall conditions have improved sufficiently to support breeding and overwintering bats.

Other recent studies that examined the predicted impact of climate change on bats include Rebello *et al.* (2010), Prydatko *et al.* (2011) and Sherwin *et al.* (2013). Rebello *et al.* (2010) modelled the potential distribution of bat diversity for three biogeographic groups: temperate, boreal and Mediterranean. Four of the ten species in their temperate group, included species reported in the current study: *P. nathusii*, *N. leisleri*, *E. serotinus* and *P. auritus*, while *N. noctula* was one of four species in their boreal group.

The measurable increased frequency of the occurrence of bats in Iceland, the Faroes, Shetland and Orkney suggests that all the above factors are important but it is difficult to distinguish between them. The importance of different factors appears to be variable depending on the study area. Overall the European migratory species are probably more likely to reach Shetland and Orkney and North Sea installations. The North American bat species seem more prone to appear in Iceland than in the other study areas. However although further away from sources of bats, whether in Europe or North America, migratory bats may well reach the Faroe Islands and Iceland as do vagrant birds (Pétursson and Skarphéðinsson, 1978) and insects (Kaaber *et al.*, 1994; Jensen, 2001).

ACKNOWLEDGEMENTS

We thank all observers for reporting their findings of bats. In Iceland Þorvaldur Björnsson has been particularly helpful in preparing and curating specimens. Thanks to Janus Hansen, FN for the loan of specimens in his care and for assistance with Fig. 1. Jerry Herman provided helpful information on specimens in the collections of the National Museums of Scotland. PJ is particularly grateful to Louise Tomsett and Roberto Portelo Miguez, Mammal Group, for preparation of skulls and for their helpful support, and to staff of the General Library for assistance in tracing obscure references. We thank reviewers for their constructive criticism of the manuscript.
